FAST AUTOTUNING OF A HYDROGEN MASER BY CAVITY Q MODULATION

G. J. Dick and T. K. Tucker
Jet Propulsion Laboratory
Pasadena, California

ABSTRACT

A new fast auto-tuner for the Hydrogen Maser has been implemented. By
modulating the cavity Q, a phase shift in the maser output signal is
induced which is proportional to the cavity tuning error. This phase shift
is detected and fed back to a varactor tuner to stabilize the cavity
against long term drifts. Cavity Q modulation has similarities to two
other auto-tuning methods, and significant advantages over both of them.
In comparison to line Q modulation, where the frequency shift induced by a
change in the atomic line Q requires a second maser for detection, the high
chopping frequency allowed by cavity Q modulation gives rise to a phase
shift which requires only the maser’s quartz crystal “flywheel” oscillator
for detection. In comparison to cavity frequency modulation, statistical
noise considerations are almost identical. However, a significant advan-
tage is the lack of phase modulation of the maser output, feedback being
around the null modulation condition. Furthermore, the Q-modulator is a
valuable analytical tool in maser alignment. Its advantage over signal
injection schemes, which give somewhat lower statistical deviation, is a
lack of systematic perturbations, including independence to connecting
cable lengths.

We have developed and tested a PIN-diode cavity Q modulator which
gives no incidental frequency shift over a very wide range of operation.
Modulated at 200 Hz, it allowed variations in maser cavity frequency to be
compensated with a loop gain greater than 1000. Compensation of incidental
amplitude modulation of the output has also been demonstrated. Calculations show that long-term stability of $3 \times 10^{-13}/\sqrt{\tau}$ should be achievable with typical masers.
GENERAL CONSIDERATIONS

The hydrogen maser is the most stable frequency source generally available today for all but the shortest measuring times. For very long measuring times \( (\tau > 10^6 \text{ seconds}) \), its performance typically deteriorates due to frequency drift of the high-Q resonant cavity necessary to sustain oscillation. Various schemes are used to detect this drift, and then to compensate for it. This can be done periodically, as part of the setup and calibration procedure, or continuously, if allowed by the procedure. Three substantially different types of auto-tuning methods have been proposed and implemented.

In spin-exchange autotuning, the linewidth or \( Q \) of the atomic hydrogen transition itself is modulated by alternating the flow of atoms into the maser cavity between two different rates. The linewidth is actually broadened by both spin-exchange and electromagnetic effects. This is because, while the changing density modulates the spin-exchange interaction with other atoms, changes in the rate induce variation in the rf amplitude, and thus also in the electromagnetic transition rate bandwidth. Since the \( Q \) of the atomic line determines the efficacy of any pulling of the oscillation away from its center frequency, such a frequency error will be modulated by the change in the hydrogen flow. The accuracy of compensation is just the accuracy with which the frequency difference between the two states of operation can be determined, divided by the fractional \( Q \) modulation. Measurement of this frequency difference to the highest possible accuracy takes 1000 seconds or more and requires a second maser with equivalent stability.

An advantage of this scheme is that, to the extent that the \( Q \) modulation is due to spin exchange, the frequency offset due to this same mechanism is also eliminated, giving increased accuracy to the tuned frequency. The principle disadvantages are the need of a second maser to use as a reference, and the relatively long term frequency shifts that result from the modulation, making maser output unusable during the tuning process.

In signal injection autotuning,\(^1\),\(^2\) the frequency offset of the cavity resonator is detected due to the difference in cavity response at two frequencies, equally spaced from the maser operating frequency, but far enough from it to prevent interference with it. The injected signals are generated by offsetting the frequency of the maser output signal and, theoretically, can be much larger in amplitude, allowing an excellent signal-to-noise ratio to be obtained for the inferred cavity frequency offset. The difficulty with signal injection methods is that nearly complete carrier suppression in the injected signal is required to prevent interference with maser operation. This is because phase instabilities anywhere in the receiver and electronics used to generate and transmit the injected rf signals will modulate the frequency-pulling effect of such a carrier. The resulting frequency offset of the maser output is given by

\[
\Delta F/F = \langle (P_c/P_h)^{1/4} / Q_h \rangle \cdot \sin \theta
\]

where \( P_h \) and \( P_c \) are the hydrogen output and injected carrier powers, res-

130
pectively, $Q_h$ is the hydrogen line $Q$, and $\phi$ is the phase difference between the injected carrier and the hydrogen signal. For a line $Q$ of $10^9$ and required frequency stability $\delta F/F = 10^{-18}$, some combination of overall phase stability and carrier suppression of 120db compared to the signal power are required by Eq 1). Since the phase of a suppressed carrier is usually not well controlled, the entire burden is placed on its magnitude. This problem has not generally been addressed by proponents of the technique.

The injected frequencies can be either applied simultaneously or sequentially. If the signals are applied together, the requirement for carrier suppression is passed on to the injection electronics in a straightforward manner. Since the main advantage of the technique is the improvement in signal-to-noise ratio that results from large injection power, a value of

$${2}$$

$$P_i/P_h = 100$$

has been proposed. From 1), and for line $Q$ and stability as above, the required carrier suppression is 140db.

For switched-frequency injection, some degree of carrier suppression results from the modulation index of ~10 implied by the operating conditions specified in Ref. 2. However, this is overcome by the larger injection power which justifies the method. At its worst, with the frequency offset $f_o$ incorrectly chosen to be an odd multiple of the modulation frequency $f_m$, carrier power for square-wave frequency modulation is given by

$${3}$$

$$P_c/P_i = (2f_m/f_o)^2$$

where $P_i$ and $P_c$ are the injected and carrier powers, giving a phase-dependent frequency variation from 1) and 2) of

$${4}$$

$$\delta F/F = (2/\pi)(P_i/P_h)^{2}(f_m/f_o)/Q_h$$

per radian of phase difference between the injected carrier and the maser oscillation. For conditions as above, and a modulation index $f_o/f_m = 11$, equation 4) implies a sensitivity of about $\delta F/F = 6 \times 10^{-10}$ per radian, an unacceptable value.

A much greater degree of carrier suppression can be accomplished by appropriately adjusting the ratio $f_o/f_m$, with the sensitivity to frequency and duty-cycle variation, and to phase variations between the switched signals depending in detail on the ratio chosen. For example, if time spent at each frequency is chosen to be an exact multiple of the period defined by the frequency offset ($f_o/f_m = 2N$), the sensitivity of the remaining carrier to a timing inaccuracy $\delta t$ can be shown to be given by

$${5}$$

$$P_c/P_i = (2 \cdot \delta t \cdot f_m)^2$$

for uncontrolled phases at the two frequencies. Restating 5) in terms of duty cycle $\eta$ and modulation frequency stabilities gives

$${6}$$

$$2 \cdot \delta \eta = \delta f_m/f_m = (P_c/P_i)^{1/2}$$

and, from 1) and 2)$$

$$= 10^{-7},$$

131
for $Q=10^9$ and $\delta F/F=10^{-15}$. If the two injected frequencies could be controlled so that they were exactly in phase at the switching points, the dependence on duty cycle would be zero to first order, a much more attractive situation. There would remain, however, a sensitivity to any A.M. at the switching points of the modulation cycle. These aspects indicate the complexity associated with any realistic solutions to the carrier suppression problem.

Cavity modulation autotuning$^3,4$ is similar to signal injection; in both cases the electromagnetic response of the cavity to microwave signals is used to determine its frequency relative to the maser operating frequency. The difference is that, instead of modulating the signal driving the cavity, some property of the cavity itself is varied. For very rapid modulations of either the cavity $Q$ or its frequency, the output signal from the hydrogen atoms remains relatively constant, resulting in a modulation of the amplitude or phase, respectively, of the cavity output signal, even when it is perfectly tuned. If the cavity is mistuned, a complementary phase or amplitude modulation results which is proportional to amount of mistuning. This can be detected by means of a phase-sensitive amplifier, and the signal used to correct the cavity frequency.

The inherent limit to performance at long averaging times for a maser stabilized in this way is determined by the phase or amplitude noise of the output signal, depending on the type of modulation used, at the modulation frequency, in relation to the signal power. In this case, the autotuning power is just that available from the maser. For frequencies of interest, namely those larger than the inverse of the hydrogen response time, the noise is typically due to the follower amplifier, being identical in phase and amplitude, and independent of the modulation frequency. For this reason, limits to performance are nearly identical for the two types of modulation. Furthermore, since this same source of noise dominates maser performance for short times, the performance possible from the stabilized maser can be directly related to that of the same unit at short times without stabilization. Calculation of this relationship is presented in the following section.

Systematic errors, while inherently smaller than for signal injection, determine many aspects of the design of the modulator. Because of the large modulation complementary to that being used to detect the cavity frequency deviation, any cross-modulation effects will give rise to inferred cavity frequency deviation, and thus to frequency errors in the stabilized system. On the other hand, variation of the magnitude of the desired modulation only causes a change in sensitivity to frequency error. As an example, if incidental frequency modulation $A_\delta=\delta F_\delta Q_\delta/F_\delta$ accompanies an intended Q-modulation $A_q=\delta Q/Q_\delta$, a systematic change in the output frequency would result given by

$$\delta F/F = (A_\delta/A_q) \cdot Q_\delta^{-1}$$

where $Q_\delta$ is the nominal cavity $Q$. Phase shifts between the modulator and cavity cause similar effects. The advantage of the modulator is that it can be constructed of a few electronic components placed directly at the maser cavity. No cable lengths need to be interposed between it and the cavity, the thermal environment is very well controlled, and the device can be designed for insensitivity to the driving signal at the designed operating points. The crucial aspects in the design of the modulator are its long-
term stability, and the sensitivity of incidental cross modulation to variation in its driving signal.

To date, long term stability measurements have only been presented for cavity frequency modulation, even though Q modulation has some substantial advantages. These include the elimination of incidental phase modulation, which is zero in the locked condition, and its availability for use to calibrate and characterize maser performance as a function of cavity Q. In a following section we present the design for such a Q-modulator and results of operational tests in a hydrogen maser. The modulator uses a PIN diode as the active element, and, when properly tuned, shows no incidental frequency modulation.

**ANALYSIS**

In this section, an analysis of autotuning by cavity modulation is presented which shows that the performance of the stabilized maser can be related in a particularly simple manner to that of the same unit at short times without stabilization. This can be done because the same additive amplifier noise limits the statistical performance in both cases. In particular, expressions are derived for the cross-over time \(T_c\), where the \(1/T\) performance which characterizes the unstabilized maser, and the \(1/4T\) stabilized performance are equal to each other. \(T_c\) has a value of approximately one second for typical conditions. Square wave modulation is explicitly included in the treatment, since this minimizes the problem of designing out systematic errors due to cross-modulation, as will be discussed in the following section. Both Q-modulation and amplitude modulation are treated, showing only small differences between them in regard to statistical properties.

The (one-sided) spectral densities of phase and amplitude fluctuations due to additive noise are equal in value and given by

\[ S_\phi(f) = S_{\phi^2}(f) = kTF/P_0 \]

where \( k \) is Boltzmann's constant, \( T \) the temperature, \( F \) the noise factor of the maser receiver, and \( P_0 \) the output power. This power is related to the more commonly used input power from the hydrogen \( P_h \) by

\[ P_0 = P_h \cdot Q_e/Q \]

where \( Q_e \) is the external Q of the cavity and \( Q \) the loaded Q. The Allan variance of frequency fluctuations in the maser output due to the effect of white phase noise as given by 8) is given by

\[ \sigma_y^2 = 3BkTF/(8\pi^2F_0P_0T^2) \]

where \( B \) is the bandwidth of the measuring system, and \( F_0 \) is the operating frequency. Note that this value is \( 3/2 \) times larger than the commonly used expression for the "variance" due to additive white noise, but which does not correspond to usual data-taking procedures.

The effect of this same noise on the variance of phase or fractional amplitude fluctuations is similarly given by
This can be directly related to a necessary uncertainty in the inferred cavity frequency, due to any phase or amplitude measurement, through the slopes of phase and amplitude with respect to frequency shown in Figure 1. The slopes indicated in the figure are the maximum in each case. For the case of phase variation it is given by

\[ \sigma_\phi^2 = \sigma_{\phi u/v}^2 = k T F_0 / (2 P_0 \tau) \]

from which the uncertainty in cavity frequency can be derived, with 11)

\[ d\phi / dF_c = 2 \phi_c / F_0 \]

If the loop is closed, inferred variations in cavity frequency will cause it to be incorrectly compensated, giving variations in the output frequency which is pulled by the cavity mistuning. Since the pulling of the output frequency is given by

\[ \delta F_o = \delta F_c Q_c / Q_h \]

which, together with 13) gives,

\[ \sigma_\gamma = \sigma_{\phi} / (2 \phi_c) \]

combining with 11) gives

\[ \sigma_\gamma^2 = \sigma_{\phi}^2 / (4 \phi_c^2 \tau) = k T F_0 / (8 P_0 Q_h \phi_c \tau) \]

for the necessary variance of fractional frequency variations under closed loop conditions. The cross-over between this expression, with a logarithmic slope of -1/2, and the unlocked maser noise given by 10) with a slope of -1 is found to be given by

\[ \tau_c = 3 Q_h^2 / (\chi^2 F_0^2) \]

which for typical conditions given by: \( B=20 \text{Hz}, \ Q_h=10^9, \ F_0=1.426 \text{GHz} \), becomes

\[ \tau_c = 3.01 \text{ seconds.} \]

Such a cross-over time is shown in Figure 2.

If the cavity were detuned so that the operating frequency lay at the point of maximum slope of the amplitude curve shown in Figure 1, a similar inference could be made as to necessary fluctuations in output frequency if measurement of the cavity frequency were inferred from the resulting amplitude. As 12) we have

\[ dv / dF_c = 4 v_o Q_c / (3^{3/2} F_0) \]

and following an identical procedure beginning again with 11), return a value for \( \sigma_\gamma^2 \) which is larger by 27/4 than that given by 16) and a value for \( \tau_c \) smaller by the same factor. This gives an apparent disadvantage to the frequency-modulation technique, but one that it recovers, as is shown
So far, this has been a calculation in principle, since no mechanism has been included to allow a measurement of the phase of the signal from the maser cavity. Figures 3 and 4 show the phase and amplitude variations \( \Delta \phi \) and \( \Delta V \) which result from rapid \( Q \) and frequency modulation in the presence of an offset between the cavity frequency \( F_c \) and operating frequency \( F_h \). Considering the case of \( Q \)-modulation explicitly, instead of

\[
\Delta \phi = 2 \Delta Q/Q_c F_c/F_o,
\]

where \( \Delta Q = \Delta Q_c/Q_c \) is the fractional \( Q \) modulation, and \( \Delta F_c \) is the frequency offset between \( F_h \) and \( F_c \). Combining with the pulling equation 14) gives, in a manner analogous to 15)

\[
\sigma_y = \sigma_{\Delta \phi}/(2 \Delta Q Q_h).
\]

The variance for the phase difference \( \sigma_\phi \) shown in Figure 3 is also not the same as that given by 11), but it is easy to evaluate for the case of square wave modulation. If one half of the time is spent in each state, the value given by 11) would double, effectively taking \( \tau \) to a new value \( \tau/2 \). The difference between two such quantities will again double the square of the variance, giving

\[
\sigma_\phi^2 = 2kT F/(\Delta Q Q_h^2 P_o\tau),
\]

which, when combined with 21), gives a value of

\[
\sigma_y^2 = kT F/(2 \Delta Q Q_h^2 P_o\tau)
\]

for the variance and

\[
\tau_c = 3B \Delta Q/Q_h^2/(4\pi^2 F_o^2)
\]

for the cross-over time. For \( \Delta Q^2 = 2 \), and the conditions as described above, a value of

\[
\tau_c = .375 \text{ seconds}
\]

is obtained, as plotted in Figure 3.

For frequency modulation, there is an apparent value to choose for the frequency deviation; it is just that which maximizes the slope. Taking that offset (a fractional displacement of \( 1/(4\Delta Q) \) of the cavity frequency), modulation as shown in Figure 4 gives a signal strength of

\[
\Delta V/V = 80 \Delta Q F_c/(3^{3/2} F_o)
\]

proportional to the frequency offset \( \Delta F_c \), as in 20). Again, accounting for the statistics of modulation we have

\[
\sigma_{\Delta V/V}^2 = 2kT F/(P_o\tau)
\]

as in 22) and
\[ \sigma_y^2 = \frac{3gKTF}{(2^5Q_h^2P_o^4)} \]

for the variance, giving, again with \ref{eq:10}.

\[ \tau_c = \frac{4BQ_h^2}{(9\pi^2F_o^2)}, \]

for the crossover time, and

\[ \tau_c = .447 \text{ seconds} \]

for the conditions as above, showing a slight advantage for the frequency modulation method. This would be reversed, if a Q-modulator could be designed which, instead of dissipating energy in the cavity, either enhanced it or transmitted it to the receiver. Variance values calculated here are somewhat higher than those estimated in Ref. 1.

The reference signal for phase measurements can be provided by a quartz crystal oscillator. As is demonstrated in Figure 2, for times corresponding to a modulation frequencies of 100Hz the phase noise from the maser, as calculated, will be the dominant contribution to measurement uncertainty.

**PIN DIODE MODULATOR**

Figures 3 and 6 show block and schematic diagrams of an autotuned maser using a PIN diode Q-modulator. Cavity tuning was accomplished using a varicap diode external to the maser physics package. The modulator itself is placed in the vacuum space and is mounted directly on the resonant cavity itself. First tests on a test-bed maser were entirely successful, with the locked loop sustaining its operation for indefinite periods of time, and for a wide variety of time constants.

In the design of the PIN-diode modulator an attempt was made to minimize as much as possible any variation of the systematic contribution of the modulator and its support equipment to the maser output frequency. To that end, it seems necessary to use square-wave modulation; while it might be possible to make the tuning properties of the modulator insensitive to the driving conditions at the end points, it would be difficult to accomplish this throughout the range of its operation.

Figure 7 shows schematically the tuning properties of three possibly useful modulators. Of these, the curve labeled C is clearly superior, with no detuning anywhere in its range. Curve B is less desirable, but still workable. It would be necessary to minimize the switching time because of detuning effects in its mid-range, but equal tuning effects at its two end points means that duty cycle sensitivity is not a problem. Curve A is clearly the worst, showing insensitivity to applied current in the highly lossy state as required, but requiring careful control of the duty cycle since frequencies at the end points are different. The zero-current state, shown at the origin, is inherently insensitive to external circuit instabilities, since the diode is in an open-circuit condition at that point. We find that, depending on its tuning, our modulator follows closely curves A or C. Its operation can be understood as follows.

If the circuit diagram for any passive device coupled to an electro-
magnetic resonator is redrawn in the form shown in Figure 8, the effect of the circuit on the properties of the resonator take a particularly simple form. In this case the loading $Q_1$ and frequency shift are given by

$$Q_1 = \frac{R_{\text{eff}} \cdot 2\pi E_C}{(\text{emf})^2}$$

and

$$\frac{\Delta f}{f} = \frac{C_{\text{eff}} \cdot (\text{emf})^2}{2E_C}$$

where $E_C$ is the energy stored in the resonator and emf is the open circuit voltage coupled to the circuit resulting from that energy and the coupling configuration. Reduced to this form, it is apparent that frequency shifts can be seen to be due only to an effective capacitance (positive or negative), and added losses only to the effective resistance.

The equivalent circuit of the PIN modulator shown in Figure 6 is given in Figure 9, showing the loop inductance $L_C$, tuning capacitor $C_t$, incidental inductance $L_i$, and the PIN diode parameters $R_p$ and $C_p$. If the capacitance $C_p$ is a constant, the circuit as shown is sufficient to give performance $C$ as shown in Figure 7. This is accomplished by tuning the variable capacitor $C_t$ so that its reactance is equal and opposite to that of the sum of the two inductances. In that case $R_{\text{eff}}$ in Figure 8 becomes $R_p$ and $C_{\text{eff}}$ becomes $C_p$. Since $C_p$ is assumed constant, only a constant frequency shift results under any circumstance, changing $R_p$ affects only the $Q$. Specifications for PIN diode parameters often show an effective parallel capacitance which has one value under back biased conditions, and another when resistive. The addition of $R_t$ in Figure 10 would allow compensation for such a characteristic.

We do not find any evidence of variation in $C_p$ as the PIN diode resistance is varied by a changing current through the diode. We chose to design the modulator for "low $Q$" operation, with the reactances associated with $L_C$ and $C_t$ about equal to the loading resistance of the diode in the "on" condition. The value of this resistance was about 100 ohms. The $Q$ of the cavity could be reduced far below its nominal "low $Q$" value by further reduction of $R_p$ to 10 ohms or below. The tuning procedure is to adjust for nominally zero frequency shift in this very low $Q$ condition where any imbalance between $L_C+L_i$ and $C_t$ is exacerbated. Using this procedure, no tuning effects could be detected between high and low $Q$ states of the modulator.

**SUMMARY AND ACKNOWLEDGEMENTS**

Analysis of several types of auto-tuning schemes has been presented with particular attention to both statistical and systematic errors in cavity-modulation and signal injection methods. Systematic variations due to incomplete carrier suppression in signal-injection methods are found to be a very substantial difficulty, probably outweighing any statistical advantage. Statistical analysis of cavity $Q$- and frequency-modulation methods show them to be essentially identical in this regard, with limiting performance shown to be directly related to that of the unstabilized maser.

A PIN-diode $Q$ modulator has been designed, constructed and tested which shows no observable incidental frequency modulation. First tests on
a test-bed maser were entirely successful, with the locked loop sustaining its operation for indefinite periods of time. Operation of this relatively low performance unit was not adversely affected in any way by the effects of the modulator. Further tests are underway.

QUESTIONS AND ANSWERS

HARRY WANG, HUGHES RESEARCH LABORATORY:
In your approximation of your frequency variance, I don't see a term for the spin exchange.

MR. DICK:
No, this is just cavity pulling, pure and simple.

MR. WANG:
But in cavity pulling, in the case of the hydrogen maser, spin exchange offset has a quadratic dependence. This is in contrast to frequency modulation, which has a linear dependence. The maser offset is linear with the cavity frequency offset. On the other hand, with Q modulation, frequency pulling is quadratic with the Q modulation.

MR. DICK:
Then if the Q modulation were not held constant, I would have an offset that varied with time. That is a good point.
